Abstract

Available high energy data for both pp and p̄p total cross sections ($5\ GeV < \sqrt{s} < 1.8\ TeV$) are described by means of two well-known distinct parametrizations, characteristic of theoretical ("Regge-like" expression) and experimental ("Froissart-Martin-like" expression) practices, respectively. Both are compared from the statistical point of view. For the whole set of present data statistical analysis ($\chi^2/d.o.f.$) seems to favour a "Froissart-like" ($(\ln s)^{\gamma\approx 2}$) rise of the total cross section rather than a "Regge-like" (s^{ϵ}) one.

Submitted to Physics Letters B

It is a well-established fact that hadronic total cross sections rise with energy ([1], [2], [7]) but the actual energy dependence of this rise is still an open question. We dispose of many parametrizations (see ref. [3], [4], [5], [6], which are by no means exhaustives) to describe the available data. Although different energy behaviours are proposed, as a matter of fact, most of them describe high energy data fairly well.

In this paper the explanation of how total cross sections grow and the predictions for future colliders energies play a secondary role. Our aim is **to compare from a statistical point of view** two characteristic parametrizations. The first is a semi-empirical parametrization, based on Regge theory and asymptotic theorems, which assumes a $(\ln s)^\gamma$ ("Froissart-like") behaviour at high-energy. It has successively been used by experimentalists to describe their data, from the ISR [4] to the S$\bar{\text{p}}$pS [13]. Moreover it has proved to be very successful in predicting the behaviour of the total cross section from the ISR to the S$\bar{\text{p}}$pS energies, in particular its considerable rising [7]. The other one, developed by Donnachie and Landshoff [3], establishes that total cross sections grow as a power of the energy: s^ϵ. Even if we know that σ^{tot} cannot ultimately grow as a power of the energy, because unitarity will break down, it is claimed that it is perfectly valid in the non-asymptotic domain which has been explored up to now. It has a sound theoretical basis on Regge theory and has successfully been applied to describe a variety of hadronic processes [11]: $\bar{\text{p}}$p, pp, $\pi^\pm$p, $K^\pm$p, γp, $\bar{\text{p}}$n, pn. It may well be considered as one of the most popular from the theoretical point of view. Its simple and compact form make it a very useful expression for representing a great variety of data as exemplified in the last version of the Review of Particle Properties [12].

In our choice we have been helped by the recent measurement of the real part of the forward elastic scattering amplitude at the S$\bar{\text{p}}$pS Collider [8]. The measurement has proved that, for the energy scale of the present accelerators, the contribution of the odd under crossing part of the scattering amplitude [9], [10] is negligible. This fact make plausible to omit all the parametrizations which include odderon effects.

Our comparative study will be done for pp and $\bar{\text{p}}$p processes only as they accumulate the most precise and energy-broader set of data. As far as the other hadronic processes are concerned the comparison between the two parametrizations in the high energy regime has much less interest due to the absence of statistics in all the cases for $\sqrt{s} > 30$ GeV [12].

Let us assume that total cross sections can be described by any of the two following expressions, hereafter called P_1 and P_2, respectively (a detailed explanation of their motivation can be found in ref. [3] for P_1, and ref. [8] for P_2):

$$\sigma_{\pm}^{tot} = A_1\ E^{-N_1}\ \mp\ A_2\ E^{-N_2}\ +\ C_0\ +\ C_2\ [ln\ (s/s_0)]^{\gamma} \tag{1}$$

$$\sigma_{\pm}^{tot} = X\ s^{\epsilon}\ +\ Y_{\pm}\ s^{-\eta} \tag{2}$$

where $+(-)$ stands for pp ($\bar{\text{p}}$p) diffusion. σ^{tot} is measured in mb and energy in GeV, being E the energy measured in the lab frame. The scale factor s_0 have been arbitrarily chosen equal to 1 GeV^2.

In P_1 the first two terms are Regge-type terms which describe the behaviour at low energy and the difference between $\sigma_{\bar{p}p}$ and σ_{pp}. The remaining ones describe the high-energy behaviour. In case $C_2 \leq \pi/m_{\pi}^2$ and $\gamma \leq 2$, this parametrization is compatible with the asymptotic Froissart-Martin bound [17].

In P_2 the first term arises from pomeron exchange and the second one from ρ, ω, f, a exchange. The coefficient X is the same for pp and $\bar{\text{p}}$p. Both ϵ and η are effective powers, slowly varying with s. Previous theoretical work indicated that ϵ should be close to 0.08 and that η is about 1/2. ¿From their analysis of pp and $\bar{\text{p}}$p data, Donnachie and Landshoff conclude that ϵ and η can be treated as constants with values $\epsilon = 0.0808$ and $\eta = 0.4525$.

In order to compare the approaches embodied in P_1 and P_2, three different kinds of fits, using three different data sets for each fit, have been performed. On each data set the first fit, F_1, is done using parametrization P_1 and the second fit, F_2, is done with P_2. In all the cases all the parameters are allowed to vary.

Furthermore, in order to make a faithful comparison with the results obtained by Donnachie and Landshoff [11] a third fit, F_3, is carried out. It is just an F_2 fit where the parameters X, Y, ϵ and η have been fixed to the values quoted by them.

For the first fit, the experimental data set consists in all available measurements of σ^{tot} and ρ, in the energy domain which spans from $\sqrt{s} = 5$ GeV up to $\sqrt{s} = 546$ GeV. The existing discrepancy between CDF (80.6 ± 2.3 mb) [14] and E710 (72.8 ± 3.1 mb) [15] total cross section measurements at the Tevatron ($\sqrt{s} = 1.8$ TeV) leads us to exclude these points from the fits. This means that we are left with 103 points.

The fits have been performed using the once-subtracted dispersion relations [16]

$$\rho_{\pm}(E)\,\sigma_{\pm}(E) = \frac{C_s}{p} + \frac{E}{\pi p}\int_m^{\infty} dE'\,p'\left[\frac{\sigma_{\pm}(E')}{E'\,(E'\,-\,E)}\;-\;\frac{\sigma_{\mp}(E')}{E'\,(E'\,+\,E)}\right] \quad (3)$$

where C_s is the substraction constant. It is a *simultaneous* fit of σ^{tot} and ρ, that is, we minimize the χ^2 function

$$\chi^2 = \chi^2_{\sigma_{\bar{p}p}} + \chi^2_{\rho_{\bar{p}p}} + \chi^2_{\sigma_{pp}} + \chi^2_{\rho_{pp}}$$

The method has proved to be very succesful in the past [4] predicting the observed rise of σ^{tot} from the ISR to the S$\bar{\text{p}}$pS. Recently it has been used, with the last data available, to provide predictions on the behaviour of σ^{tot} up to $\sqrt{s} = 100$ TeV [13]. A detailed study of the technique can be found in [18].

In F_1 we are left with eight free parameters (A_1, N_1, A_2, N_2, C_0, C_2, γ, C_s). For the F_2 we have six free parameters (X, Y_+, Y_-, η, ϵ, C_s). Finally in F_3 we have only one free parameter (C_s).

Table 1 shows the values of the parameters obtained for the best F_1, F_2 and F_3 fits. Table 2 quotes, for these best fits, the values of χ^2 and $\chi^2/d.o.f.$ We have included also the predicted numerical values for σ^{tot} for each of the three considered cases at the energies of the S$\bar{\text{p}}$pS, Tevatron and LHC. In table 3 the experimental values of σ^{tot} at the S$\bar{\text{p}}$pS and Tevatron are compared to the predictions of F_1, F_2, and F_3.

It clearly appears that F_1, with the dominant $(\ln s)^{\gamma\approx 2}$ term at high energies ($\chi^2/d.o.f. = 0.8$) gives by far the best result. It perfectly matches the S$\bar{p}$pS measured value. It is interesting to observe that its prediction at the Tevatron lies right at the middle (76.5 ± 2.3 mb) of the conflicting claims for σ^{tot} of both Tevatron experiments, CDF and E710. As for F_2, even if it may be considered as an acceptable fit ($\chi^2/d.o.f. = 1.6$) it has, at least, two difficulties: on the one hand, the values obtained for ϵ, 0.0644 ± 0.0015, and η, 0.5433 ± 0.0075, represent a challenge for the model. They are far away from their theoretical estimations quoted previously. And, on the other hand, the numerical values obtained for σ^{tot} (see table 2), being much lower than the measured ones, rule it out. Finally F_3 is clearly *statistically* ruled out ($\chi^2/d.o.f. = 4.5$) with respect to the others fits, although its σ^{tot} predictions might appear acceptable. Indeed, Donnachie and Landshoff considered a definite success of their parametrization the prediction, in 1985 [19], of about 73 mb for σ^{tot} at the Tevatron. As we have said, the accepted value of σ^{tot} at 1.8 TeV is far from clear up to now. Waiting for the measurement of σ^{tot} at the LHC we find this parametrization statistically unsupported by present data.

In our second step, the fits are less powerful: we restrict them to the σ_{pp}^{tot} and $\sigma_{\bar{p}p}^{tot}$ experimental data sample (69 points), excluding the $\rho_{\bar{p}p,pp}$ measurements, which is the usual practice. Now we have seven free parameters for F_1 and five for F_2. In this case, F_3 is not a real fit because we do not minimize χ^2.

Table 4 shows the parameters as given by the best fits and table 5 gives in addition to χ^2 and $\chi^2/d.o.f.$, the values for σ^{tot} at the energies of the S$\bar{p}$pS, Tevatron and LHC.

In figure 1 we have depicted the results of these three fits together with the experimental data on σ^{tot}. Recent cosmic rays results [20] from the Akeno Observatory obtained from the analysis of proton-air interactions at ultrahigh energies are also plotted.

The results show no sensible changes with respect to the ones of the previous step and the same discussion applies. Again F_1 is strongly supported by the data, which is not the case for F_2. F_3 yields, once again, σ^{tot} predictions consistent with current experimental evidence, but its large $\chi^2/d.o.f.$ value rules it out from the statistical point of view.

Finally we investigate how the variation of the energy domain influences the results previously obtained. We restricted the fits to a smaller energy domain, in the sense of increasing energy, $10 \leq \sqrt{s} \leq 546$ GeV, but still keeping enough data (42 points) to make results sensible.

The trend previously observed are, in spite of the bigger statistical errors due to the smaller number of data points, not altered: the results for the different fits are practically the same as an inspection of tables 6 and 7 shows. F_1 always gives the lowest $\chi^2/d.o.f.$ value. F_2 does not reproduce the experimental points and F_3 , which does better than F_2, has the worst χ^2 of all three fits.

In conclusion, although it is claimed that $(\ln\, s)^{\gamma\approx 2}$ and $s^{0.0808}$ rises adequately reproduce high-energy pp and $\bar{\rm p}$p data, from a careful analysis of present experimental evidence, we have shown that statistically a $(\ln\, s)^{\gamma\approx 2}$ fit is strongly favoured. Better $\chi^2/d.o.f.$ may be obtained, in the s^ϵ model, at the price of lower ϵ values, but for these cases the resulting σ^{tot} values are clearly unrealistic.
